We review the confinement scenario in Coulomb gauge. We show that when thin center vortex configurations are gauge transformed to Coulomb gauge, they lie on the common boundary of the fundamental modular region and the Gribov region. This unifies elements of the Gribov confinement scenario in Coulomb gauge and the center-vortex confinement scenario. We report on recent numerical studies which support both of these scenarios.

## 1. Introduction

In a confining theory such as QCD it is helpful to choose a gauge which makes the confining mechanism transparent. In the present article we shall be primarily concerned with the confinement scenarios in minimal Coulomb gauge and in maximal center gauge, and with the unification of elements of these two scenarios.

The Landau gauge has the simplest Lorentz transformation properties, but there is at present no confinement scenario in Landau gauge. The obstacle is that the gluon propagator is of shorter range in Landau gauge than it is in a free theory, because of the suppression of the low-momentum components by the proximity of the Gribov horizon (see below). This makes the mechanism of confinement of color charge in Landau gauge more rather than less mysterious. We turn instead to the Coulomb gauge.

Confinement of color charge is easily understood in minimal Coulomb gauge because the 0-0 component of the gluon propagator,

$$D_{00}(x, t) = V_{\text{coul}}(|x|) \delta(t) + \text{non-instantaneous}, \quad (1)$$

has an instantaneous part,  $V_{\text{coul}}(r)$ , that is long range

\*Talk given by D. Zwanziger at *QCD Down Under*, Adelaide, Australia, March 10–19, 2004. Research is supported in part by the U.S. Department of Energy under Grant No. DE-FG03-92ER40711 (J.G.), the Slovak Grant Agency for Science, Grant No. 2/3106/2003 (Š.O.), and the National Science Foundation, Grant No. PHY-0099393 (D.Z.).

and confining and couples universally to all color-charge. We call  $V_{\text{coul}}(r)$  “the color-Coulomb potential”. Moreover the 3-dimensionally transverse would-be physical components of the gluon propagator,

$$D_{ij}(x, t) = \langle A_i(x, t) A_j(0, 0) \rangle, \quad (2)$$

are short range, corresponding to the absence of gluons from the physical spectrum. We shall review recent numerical evidence [1–3] which strongly supports these statements.

The Coulomb gauge has also been studied vigorously in the hamiltonian formalism [4].

## 2. Definition of minimal Coulomb gauge

In minimal Coulomb gauge, the representative  $A_i(x)$  of each gauge orbit (at a fixed time  $t$ ) is the absolute minimum of a minimizing functional with respect to gauge transformations. The minimizing functional is taken to be

$$F_A(g) \equiv ||^g A||^2 \quad (3)$$

where the gauge transform is given by

$$^g A_i = g^{-1} A_i g + g^{-1} \partial_i g, \quad (4)$$

and the Hilbert norm by,

$$||A||^2 = \int d^3x \sum_i^a |A_i^a(x)|^2. \quad (5)$$

This kernel has the explicit form

$$K_{xy}^{ab}(A) \equiv [M^{-1}(A)(-\nabla^2)M^{-1}(A)]_{xy}^{ab}, \quad (16)$$

where  $M(A)$  is the Faddeev–Popov operator (10).

It follows that if  $V(R)$  is confining,

$$\lim_{R \rightarrow \infty} V(R) = \infty, \quad (17)$$

then the color-Coulomb potential,  $V_{\text{coul}}(R)$ , is confining,

$$\lim_{R \rightarrow \infty} V_{\text{coul}}(R) = \infty. \quad (18)$$

Moreover if both increase linearly at large  $R$ ,  $V(R) \sim \sigma R$ ;  $V_{\text{coul}}(R) \sim \sigma_{\text{coul}} R$ , then

$$\sigma_{\text{coul}} \geq \sigma. \quad (19)$$

We conclude that in the confining phase the 2-point function  $V_{\text{coul}}(R)$  is confining.

Greensite and Olejnik [1] determined the color-Coulomb potential  $V_{\text{coul}}(R)$  numerically from the lattice quantity

$$\begin{aligned} G(|x|) &\equiv \frac{1}{2} \langle \text{Tr}[U_0^\dagger(x, t) U_0(0, t)] \rangle, \\ V_{\text{coul}}(R) &= -\ln G(R). \end{aligned} \quad (20)$$

They found an impressively linear behavior of the color-Coulomb potential  $V_{\text{coul}}(R)$ . The relevant figure is presented in Greensite’s talk at this meeting [7].

## 5. Confinement scenario in Coulomb gauge

To see why  $V_{\text{coul}}(R)$  is long range, consider formula (16) for the kernel  $K_{xy}^{ab}(A)$ . Recall that  $M(A)$  is strictly positive in the interior of the Gribov region  $\Omega$ , and develops a zero eigenvalue on its boundary (the Gribov horizon),

$$\begin{aligned} M(A) &> 0 \text{ for } A \text{ inside } \Omega, \\ M(A)\phi_0 &= 0 \text{ for } A \text{ on } \partial\Omega. \end{aligned} \quad (21)$$

By continuity,  $M(A)$  has a small eigenvalue for configurations near the boundary. As explained below, the population is concentrated close to the boundary  $\partial\Omega$ . This enhances  $M^{-1}(A)$ , and thus also  $K_{xy}^{ab}(A)$ , which makes  $V_{\text{coul}}(R)$  long range. A more sophisticated discussion, given below, explains the long range of  $V_{\text{coul}}(R)$  in the infinite-volume limit in terms of the density of states  $\rho(\lambda)$  of the Faddeev–Popov operator  $M(A)$ .

As already noted by Gribov [8], the Gribov horizon is close by in directions (in  $A$ -space) that correspond to low-momentum Fourier components of the gluon field  $A$ . This suppresses the low-momentum parts of *all* Lorentz components of the gluon propagator  $D_{\mu\nu}$  in minimal Landau gauge. While this eliminates gluons from the physical spectrum, it makes it harder to explain confinement of colored quarks. For the same reason, in minimal Coulomb gauge, restriction to the interior of the Gribov horizon *suppresses* the low-momentum components of the would-be physical, 3-dimensional gluon propagator  $D_{ij}(x, t)$ , which eliminates physical gluons from the physical spectrum. However, as we have just seen, in Coulomb gauge it also *enhances*  $V_{\text{coul}}(|x|)$ , which is the instantaneous part of  $D_{00}$  in Coulomb gauge. This couples universally to all colored objects, and is a prime candidate to trigger confinement. Thus we can have our cake and eat it: physical gluons are suppressed because  $D_{ij}$  is short range, while  $D_{00}$  is long range and can cause confinement.

## 6. Double boundary dominance

The dimension  $D$  of  $A$ -space in the presence of the lattice cut-off is a large number, of the order of the volume of the lattice  $D \sim L^4$ , and in a space of high dimension the volume density goes like  $r^{D-1} dr$ . We thus expect on entropy grounds that (a) the population is concentrated close to the boundary  $\partial\Lambda$ . However, as we have just seen, the enhancement of  $V_{\text{coul}}(R)$  occurs if (b) the population is concentrated close to the boundary  $\partial\Omega$ . However  $\Lambda$  is a subset of  $\Omega$ ,  $\Lambda \subset \Omega$ , so (a) and (b) are compatible only if (c) the population is concentrated where the 2 boundaries coincide, i.e.  $\partial\Lambda \cap \partial\Omega$ .

Why should this be? We present an explanation in terms of dominance of center vortices, and thereby unify elements of the Gribov confinement scenario in Coulomb gauge and the center-vortex confinement scenario. The latter is reviewed in [9].

## 7. Thin center vortex configurations lie on the double boundary

Definition: we call a “thin center vortex configuration” any lattice configuration for which every link variable is a center element,  $U_{x,i} = Z_{x,i}$ . The uni-

fication of elements of the Gribov and center-vortex scenarios follows from the fact [2] that when a center configuration  $Z$  is gauge transformed to the minimal Coulomb gauge  $Z \rightarrow U = {}^g Z \in \Lambda$  it lies on the common boundary,  $U \in \partial\Omega \cap \partial\Lambda$ . The proof is sketched below. It follows that center vortex dominance implies dominance by a subset of this common boundary.

Note: The same statement and conclusion hold also for abelian configurations.

### 8. Thin center vortex configurations lie on singular gauge orbits

Thin center vortex configurations and their gauge transforms  $U = {}^g Z$  may be characterized in a gauge-covariant way as possessing non-zero solutions  $\phi_n$

$$D(U)\phi_n = 0, \quad (22)$$

where  $n = 1, \dots, N^2 - 1$  for  $SU(N)$ , and  $D(U)$  is the generator of a gauge transformation, defined by

$${}^g U = U + \epsilon D(U)\phi, \quad (23)$$

where  $g = 1 + \epsilon\phi$  is an infinitesimal gauge transformation. Indeed, center configurations are invariant,  ${}^h Z = Z$ , under the  $N^2 - 1$  linearly independent global ( $x$ -independent) gauge transformations  $h$ . For  $h = 1 + \epsilon\phi$  this gives the gauge-covariant condition  $D(Z)\phi = 0$ .

Note: Similar properties hold for abelian configurations, with  $n = 1, \dots, R$ , where  $R$  is the rank of the gauge group.

*Proof that a thin center vortex configuration lies on the double boundary:* The equation  $D(Z)\phi_n = 0$ , being gauge covariant, holds after transformation to minimal Coulomb gauge,  $U = {}^g Z$ , so  $U \in \Lambda$ , and with  $\psi_n = {}^g \phi_n$ , we have  $D(U)\psi_n = 0$ . It follows that the  $\psi_n$  are null vectors of the Faddeev–Popov operator

$$-\nabla_i D_i(U)\psi_n = 0, \quad (24)$$

so  $U = {}^g Z$  lies on the boundary of the Gribov region,  $U \in \partial\Omega$ . We also have  $U \in \Lambda$ , and since  $\Lambda \subset \Omega$ , it follows that  $U$  lies on the double boundary,  $U \in \partial\Lambda \cap \partial\Omega$ , as asserted.

The gauge orbit of a thin center configuration is a geometrically singular gauge orbit. It has  $N^2 - 1$ , fewer dimensions than a generic gauge orbit, because

${}^g U = U$  for  $g(t) = \exp(t\phi_n)$ . By contrast, the Gribov horizon  $\partial\Omega$  is, in general, merely a coordinate singularity.

### 9. Numerical tests of center vortex dominance in Coulomb gauge

In [3] the hypothesis of center vortex dominance was tested by the following procedure [10]. (1) Configurations are fixed to the maximal center gauge. (2) In this gauge, a thin center-vortex configuration is defined, for  $SU(2)$ , by

$$Z_{x,\mu} = \text{sign}[\text{Tr}(U_{x,\mu})], \quad (25)$$

and a “vortex-removed” configuration by

$$\tilde{U}_{x,\mu} = Z_{x,\mu} U_{x,\mu}. \quad (26)$$

(3) Finally, the resulting center-projected configuration  $Z_{x,\mu}$  and the vortex-removed configuration  $\tilde{U}_{x,\mu}$  are gauge transformed to the minimal Coulomb gauge. According to the center vortex scenario, the projected center configurations should retain the confining properties, whereas the vortex-removed configurations should be non-confining.

The color-Coulomb potential  $V_{\text{coul}}(R)$ , defined in (20) was determined numerically in [1], for both the full configuration and the vortex removed configuration. The relevant figure is reproduced in Jeff Greensite’s talk at this meeting [7]. One sees that the color-Coulomb potential is impressively linear for the full configuration, as noted above, but is flat for the vortex-removed configurations. This confirms the center-vortex scenario.

A more detailed test of the center-vortex scenario comes from a study [3] of the density  $\rho(\lambda)$  of the eigenvalues  $\lambda$  of the Faddeev–Popov operator (10). This quantity appears in the formula for the Coulomb or unscreened self-energy of a static color-charge at infinite lattice volume that follows from (14) and (16),

$$\mathcal{E} = \int_0^{\lambda_{\text{max}}} \frac{d\lambda}{\lambda^2} \langle \rho(\lambda) F(\lambda) \rangle, \quad (27)$$

where  $F(\lambda) \equiv \langle \lambda | (-\nabla^2) | \lambda \rangle$  is the diagonal matrix element of  $(-\nabla^2)$  in the Faddeev–Popov eigenstates  $|\lambda\rangle$ . The Coulomb energy is infrared divergent, as it should be in the confined phase, if, at infinite volume,

$$\lim_{\lambda \rightarrow 0} \frac{1}{\lambda} \langle \rho(\lambda) F(\lambda) \rangle > 0. \quad (28)$$

Figure 2. The F-P eigenvalue density at  $\beta = 2.1$ , on  $8^4 - 20^4$  lattice volumes.

Figure 3.  $F(\lambda)$ , the diagonal matrix element of  $(-\nabla^2)$  in F-P eigenstates, plotted vs. F-P eigenvalue.

The quantities  $\rho(\lambda)$  and  $F(\lambda)$  were determined numerically [3] for the full configurations, for center-projected (vortex-only) configurations and vortex-removed configurations, each of which have been transformed to Coulomb gauge.

Figures 2 and 3 show the results for  $\langle \rho(\lambda) \rangle$  and  $\langle F(\lambda) \rangle$  for the full configurations, on a variety of lattice volumes ranging from  $8^4$  to  $20^4$ . The apparent sharp “bend” in  $\rho(\lambda)$  near  $\lambda = 0$  becomes increasingly sharp, and happens ever nearer  $\lambda = 0$ , as the lattice volume increase. The impression these graphs convey is that in the limit of infinite volume, both  $\rho(\lambda)$  and  $F(\lambda)$  go to positive constants as  $\lambda \rightarrow 0$ . However, for both  $\rho(\lambda)$  and  $F(\lambda)$  we cannot exclude the possibility that the curves behave like  $\lambda^p$ ,  $\lambda^q$  near  $\lambda = 0$ , with  $p, q$  small powers.

Next we consider the same observables for the “vortex-only” configurations, consisting of thin center vortex configurations transformed to Coulomb gauge. The data for  $\langle \rho(\lambda) \rangle$  and  $\langle F(\lambda) \rangle$  at the same range ( $8^4 - 20^4$ ) of lattice volumes are displayed in

Figure 4. F-P eigenvalue density in vortex-only configurations.

Figure 5.  $F(\lambda)$ , the diagonal matrix element of  $(-\nabla^2)$  in F-P eigenstates, for vortex-only configurations.

Figs. 4 and 5. The same qualitative features seen for the full configurations, e.g. the sharp bend in the eigenvalue density near  $\lambda = 0$ , becoming sharper with increasing volume, are present in the vortex-only data as well, and if anything are more pronounced.

Finally, we consider the same observables for the vortex-removed configurations, transformed to Coulomb gauge. Results are shown in Fig. 6 for  $\langle \rho(\lambda) \rangle$ . The behavior is strikingly different, in the vortex-removed configurations, from what is seen in the full and vortex-only configurations. The graph of  $\langle \rho(\lambda) \rangle$ , at each lattice volume, shows a set of distinct peaks, while the data for  $\langle F(\lambda) \rangle$  (not shown) is organized into bands, with a slight gap between each band. Inspection shows that eigenvalue interval associated with each band in  $\langle F(\lambda) \rangle$  precisely matches the eigenvalue interval of one of the peaks in  $\langle \rho(\lambda) \rangle$ .

In order to understand these features, consider the eigenvalue density of the Faddeev–Popov operator  $M_{xy}^{ab} = \delta^{ab}(-\nabla^2)_{xy}$  appropriate to an abelian the-

ory, or a non-abelian theory at zeroth order in the coupling. At finite lattice volume, this operator has degenerate eigenvalues, and we call  $N_k$  the degeneracy of its  $k$ -th eigenvalue  $\lambda_k$ . When the degeneracies  $N_k$ , of the zeroth-order Faddeev–Popov eigenvalues are compared with the number of eigenvalues per lattice configuration found inside the  $k$ -th “peak” of  $\langle\rho(\lambda)\rangle$ , and  $k$ -th “band” of  $\langle F(\lambda)\rangle$ , there is a precise match. This leads to a simple interpretation: the vortex-removed configuration  $\tilde{U}_\mu$  can be treated as a small perturbation of the zero-field limit  $U_\mu = I$ . This perturbation lifts the degeneracy of the  $\lambda_k$ , spreading the degenerate eigenvalues into the peaks of finite width in  $\langle\rho(\lambda)\rangle$  seen in Fig. 6. For the vortex-removed configurations, both  $\langle\rho(\lambda)\rangle$  and  $\langle F(\lambda)\rangle$  seem to be only a perturbation of the corresponding zero-field results.

We conclude that it is the vortex content of the thermalized configurations which is responsible for the enhancement of both  $\rho(\lambda)$  and  $F(\lambda)$  near  $\lambda = 0$ , leading to an infrared-divergent Coulomb self-energy.

## 10. Conclusion

We have seen that when thin center vortex configurations are gauge transformed to the minimal Coulomb gauge they lie on the double boundary of the Gribov region and the fundamental modular region. This unifies elements of the Gribov confinement scenario in minimal Coulomb gauge and the center-vortex confinement scenario.

Our numerical study [3] reveals the following features:

(1) The data are consistent with a linearly rising color-Coulomb potential,  $V_{\text{coul}}(R) \sim \sigma_{\text{coul}} R$ , and a Coulomb string tension that is larger than the physical string tension,  $\sigma_{\text{coul}} > \sigma$ .

(2) The data are compatible with a density of eigenvalues  $\rho(\lambda)$  of the Faddeev–Popov operator with either  $\rho(0)$  finite, or with  $\rho(\lambda) \sim \lambda^p$ , for small  $\lambda$ , where  $p$  is close to zero. This feature, and the value of  $\langle\rho(\lambda)F(\lambda)\rangle$  at small  $\lambda$ , provide detailed verification of the Gribov confinement scenario in Coulomb gauge.

(3) These confining features are preserved by the “vortex-only” configurations, but are replaced by features close to a free theory in the “vortex-removed” configurations. This is consistent with center vor-

Figure 6. F-P eigenvalue densities for vortex-removed configurations, on a  $20^4$  lattice volume.

tex dominance. This, in turn, implies the condition of double boundary dominance that accords with the Gribov scenario in minimal Coulomb gauge.

Finally, we refer to [3] for a similar numerical investigation of the gauge field coupled to a Higgs field, and of pure gauge theory at finite temperature in the deconfined phase.
